Abstract: Many methods based on machine vision were used to estimate coarse particles size distribution in recent years, but comparison of accuracy parameters representing particle size has not been carried out and a related representing analysis has not been yet proposed. Nine parameters were investigated. The results indicated the minor axis of equivalent ellipse and breadth of the best-fit rectangle were the most suitable for representing particle size. The former accuracy ratio was 86.43% and the latter accuracy ratio was 85.39%, while the accuracy of other parameters was less than 70%. A related representing analysis was proposed to explain this phenomenon. This research is instructive and meaningful for the size distribution estimation by machine vision.

Keywords: machine vision, particle size distribution, equivalent ellipse, best-fit rectangle, representing analysis

Introduction

Particle size and size distribution are important variables in many industrial sectors (Tasdemir et al., 2011; Zhang et al., 2012), especially in mining and mineral processes. Most mineral processing operations rely on the size distributions measurement as a key factor in improving process efficiencies (Xia et al., 2012a; Xia et al., 2012b). Sieving has been used to measure particle size distribution traditionally, but it is very time-consuming and cannot be quick enough to provide real-time feedback information to direct production. So machine vision has been used for particle size measurement in the last twenty years.

Many problems such as the way of image acquisition, the algorithm of image segmentation, parameters of particle size and error correction of the system had all been extensively investigated in recent years. However, a comparison of all parameters in accuracy aspect has not been carried out and related representing analysis has not yet proposed. Authors argue that the size parameters extracted from images to represent
sieving particle size should satisfy two demands, i.e., be rotationally-invariant and have a selecting basis.

In image analysis, different ways of measuring particle size, such as equivalent circle diameter (Maerz et al., 1987; Medermott et al., 1989; Grannes et al., 1986; Donald and Kettunen, 1996; Maerz et al., 1996; Rholf et al., 1993), maximum size (Montserrat et al., 1993; Ord et al., 1989; Kemeny et al., 1994), size of equivalent ellipse (Girdner et al., 1996; Schleifer et al., 1993), Ferret diameter (Kwan et al., 1999; Mora et al., 1998; Mora et al., 2000; Al-Thyabat et al., 2006; Al-Thyabat et al., 2007) and best-fit rectangle (Wang, 2006; Tobias et al., 2012) have been used. All the above parameters are rotationally-invariant, but are optionally selected to estimate size distribution with no representing analysis and selecting basis.

In this paper, 467 coal particles in four size fractions were selected through a strict screening to compare the accuracy of the above mentioned parameters, and a representing analysis combined with a screening principle was proposed to explain the results.

Experiments

Sample preparation

The experiment sample was anthracite coal from the Tai-Xi coal preparation plant in China. Basically, the sieving operation attempts to divide the coal sample into fractions, each consisting of particles within specific size limits. In China’s coal cleaning standards, the mesh apertures are 100, 50, 25, 13, 6, 3, 0.5 mm. When necessary, the mesh apertures can increase or decrease, so a series of sieves with square apertures 3, 6, 13, 25, 50 mm were used in our experiment. As to the coal particles smaller than 3 mm, the outline accuracy by digital image processing is low, and the particles greater than 50 mm are not suitable for experiment and test. For the reasons given above, the particles smaller than 3 mm and greater than 50 mm were discarded. 120 particles (3–6 mm), 146 particles (6–13 mm), 109 particles (13–25 mm) and 92 particles (25–50 mm) were selected to accomplish this research.

Image acquisition and parameters calculation

A high quality picture of the coal particles is needed before any digital image processing is performed. Some researchers noted the shadows cast by the objects, and the interior texture could be confusing to edge detection algorithms (Wang, 2006; Guyot et al., 2004; Casali et al., 2001). A backlit system, shown in Fig. 1A, was built to eliminate these problems. This system was designed as a closed box for avoiding the outside light effect. Digital camera (Nikon S220) was put in the camera hole of this system, and we fixed the height from the hole to the platform as 41.5 cm, just right above of the sample platform. Four fluorescent lamps (TCL 8W) were set equidistantly under the sample platform. Figure 1B is an image of one coal particle taken in the normal daylight, and Fig. 1C is an image of the same coal particle taken in the
backlit system. It is obvious that the image taken in the backlit system can eliminate the shadow and the interior texture, which provide a good basis for extracting features accurately.

The pixel size of the captured image is 1024×768. The image from Fig. 2 (A) was used to measure the shooting coverage and the conversion ratio between pixel size and actual size. The shooting coverage is 366 mm×274.5 mm, and one pixel is approximately equal to 0.357 mm. When the coal particles are placed on the sample platform, they are carefully spread out, making certain that they are in the stable position and without touching or overlapping each other to insure the accurate edge extraction. Figure 2 (B) is a gray histogram of the image after removing the ruler seen in Fig. 2 (A). The optimal threshold was determined manually as 50 for the twin-peaks method. Sometimes there will be several dirty spots or dust on the platform. In this case the area threshold will be used to remove these isolated micro-regions and filling processes will be used to fill the interior of particles completely. Through the above image processes, all our images can be segmented accurately, like in Fig. 2(C). In this part, some researchers used some methods to segment images, like filtering, dilating, eroding, top-hat, bottom-hat and watershed and so on (Al-Thyabat et al., 2007; Banta et al., 2003). Many morphological processes will cause an inaccurate outline of particles because the regions handled by structure elements chosen in these operations may be changed, especially during dilating and eroding processes. So, we used in our experiments no touching particles and the simple but credible segmentation method to insure the experiment precision.

Nine parameters were investigated. A sketch map of parameters which are easy to express were shown in Fig. 2(D):

- $D_A$ – equivalent circle diameter: the circle area is equal to the target area,
- $D_{\text{max}}$ – maximum size: the maximum distance between two pixels on the perimeter,
- $D_{\text{major}}$ – major axis of equivalent ellipse: the length of the major axis of the ellipse that has the same normalized second central moments as the target region,
$D_{\text{minor}}$ – minor axis of equivalent ellipse: the length of the minor axis of the ellipse that has the same normalized second central moments as the target region,

$D_{\text{mean1}}$ – the average of $d_{\text{major}}$ and $d_{\text{minor}},$

$D_F$ – Ferret’s diameter: the mean value of distances cross the centroid between two parallel tangents which are on opposite sides of the target region in $0^\circ$, $45^\circ$, $90^\circ$ and $135^\circ,$

$D_B$ – the breadth of best-fit rectangle of target region. The method of best-fit rectangle is a combination of the Ferret method and the least 2nd moments minimization, requiring only calculation of the three moments about the center of gravity, and maximum and minimum co-ordinates in a co-ordinate system oriented in the direction of the axis of the least 2nd moments, and a simple area ratio (Weixing, 2006),

$D_L$ – the length of best-fit rectangle of target region,

$D_{\text{mean2}}$ – the average of $d_B$ and $d_L.$

Fig. 2. Image acquisition and processing: (A) coal particles image taken in the backlit system, (B) gray histogram of image after removing ruler in the image (A), (C) binary of image (B) processed by twin-peaks method and removing isolated points, (D) sketch map of $D_A$, $D_F$, $D_B$, $D_L$, $D_{\text{max}}$, $D_{\text{major}}$ and $D_{\text{minor}}$

In order to test and verify the accuracy of this image technique, the length and breadth of best-fit rectangle were used to carry out the comparison. A vernier caliper, minimum range of which is 0.02 mm, was used to measure the actual length and breadth of best-fit rectangle according to the rectangular position after image proc-
esses, like Fig. 3A. Figures 3B and 3C show the actual measurement of breadth and length of one coal particle. Twelve coal particles, three in each size fraction, were chosen randomly to test and verify the accuracy using the above method, and the results were shown in Table 1. The average and variance of absolute value of errors were 0.23 mm and 0.03 mm², respectively, indicating that the difference between actual size and estimated size is small. Furthermore, the T-test was used to verify whether the average error is zero. The significance level \( \alpha \) is determined as 0.05. The T-value and p-value are 0.4934 and 0.6264, respectively, indicating that the average error can be considered as zero in the above significance level, that is, the errors’ fluctuation is normal. All the results show that the accuracy of this image analysis is high and satisfied.

Results and discussion

Totally 467 coal particles in four size fractions were selected through strictly screening to compare the accuracy of the investigated nine parameters. The accuracy ratio of each parameter in each size fraction was calculated as follows:

\[
\text{Accuracy ratio} = \frac{\text{Correct number}}{\text{Total number}} \times 100\%. \tag{1}
\]

The results shown in Fig. 4 indicate that \( D_{\text{minor}} \) and \( D_B \) were more suitable to represent the real particle size. The mean value of \( D_B \) accuracy ratio is 86.43\%, and the mean value of \( D_{\text{minor}} \) accuracy ratio is 85.39\%. The others were no more than 70\%.

Particle is a 3-D object having length, width and thickness. \( D_{\text{minor}} \) and \( D_B \) were like the width of particles. Width must be smaller than the length. Weixing (2006) indicated that the particle width distribution curve is between the length and thickness curves. Authors verified this phenomenon previously. The real thicknesses of 496 particles were calculated by their real mass, real density and projected area. The width is instead of the breadth of the best-fit rectangle because it is near the real width. Figure 5 shows the results of comparing the real thickness and the breadth of the best-fit rectangle, indicating most particles’ thickness are smaller than the width.

In the process of on-line analysis, particles are constantly shaking on the belt, so most particles stand on the stable side, i.e. sit on the biggest bottom area of particle. Of course the collision between particles will also affect the particle standing way. In the laboratory, particles lie mostly on the biggest bottom area, so length and width of the projected area are almost bigger than particle thickness. Thus:

\[
\text{Thickness} \leq \text{Width} \leq \text{Length}.
\]

When particles pass through a screen hole, according to the screening principle, there are two sizes smaller than the size of the screen hole. Therefore, the width of the particle determines whether this particle can pass through the screen hole. The values of \( D_{\text{minor}} \) and \( D_B \) are near the width of particles, so they are accurate for the analysis.

Conclusion

A set of 496 particles was selected from four size fractions by accurate sieving to compare the accuracy of representing the particle size by nine parameters. Results indicated the \( D_{\text{minor}} \) and \( D_B \) were the most suitable to represent the real particle size. The mean value of \( D_B \) accuracy ratio was 86.43\%, and the mean value of \( D_{\text{minor}} \) accuracy ratio was 85.39\%. The mean values of others parameters were no greater than 70\%. The representing analysis combined with screening principle was proposed to
